- Museum curators, collection managers, and private collectors

- Sensitive indicators of water quality

- Ranges of species shrinking all over world

- Third most imperiled animal group in USA

- High percentage of extirpations/extinctions in Illinois

- Have the same losses occurred in Midwest?

What Are The Challenges to Reconstructing Distributions?

- Range loss has already occurred
- Published distributions are often inadequate:
 - Lack vouchers
 - Obsolete taxonomy
 - Low taxonomic resolution
 - Incomplete location information
- Where do we get data adequate for the question?

Museum Specimens Are a Source of Data

Pros	Cons
Oldest records/greatest range	Presence data-only
Identifications verifiable	Sample effort unclear
Many specimens available	Some inexact locations

*Imperfect data, yes,
but often the best
available!*

Objectives

Reconstruct the historic range of stoneflies in Midwest

- Characterize fauna
- Predict ranges of individual species
- Predict species richness patterns

Methods

- New samples in intact habitat
 - Multi-season
 - Adults and nymphs, rearing
 - Multi-method
- Museum specimens from regional institutions
 - 25 museums
 - ID to current standards
 - Digitize: unique identifier, verbatim, value added
 - Return fully curated collection and data
- Characterize assemblage
 - Observed richness in HUC6 drainages
 - Estimate S richness predictions and rare species

Single Species Distribution Modeling

- Environmental variables
 - Scale: 8700 HUC12 drainages, ~20,000 acres
 - 300 variables, eco-hydrology & historical vegetation
 - Variable reduction through cluster analysis

Producing “**Full Model**” for using Maxent

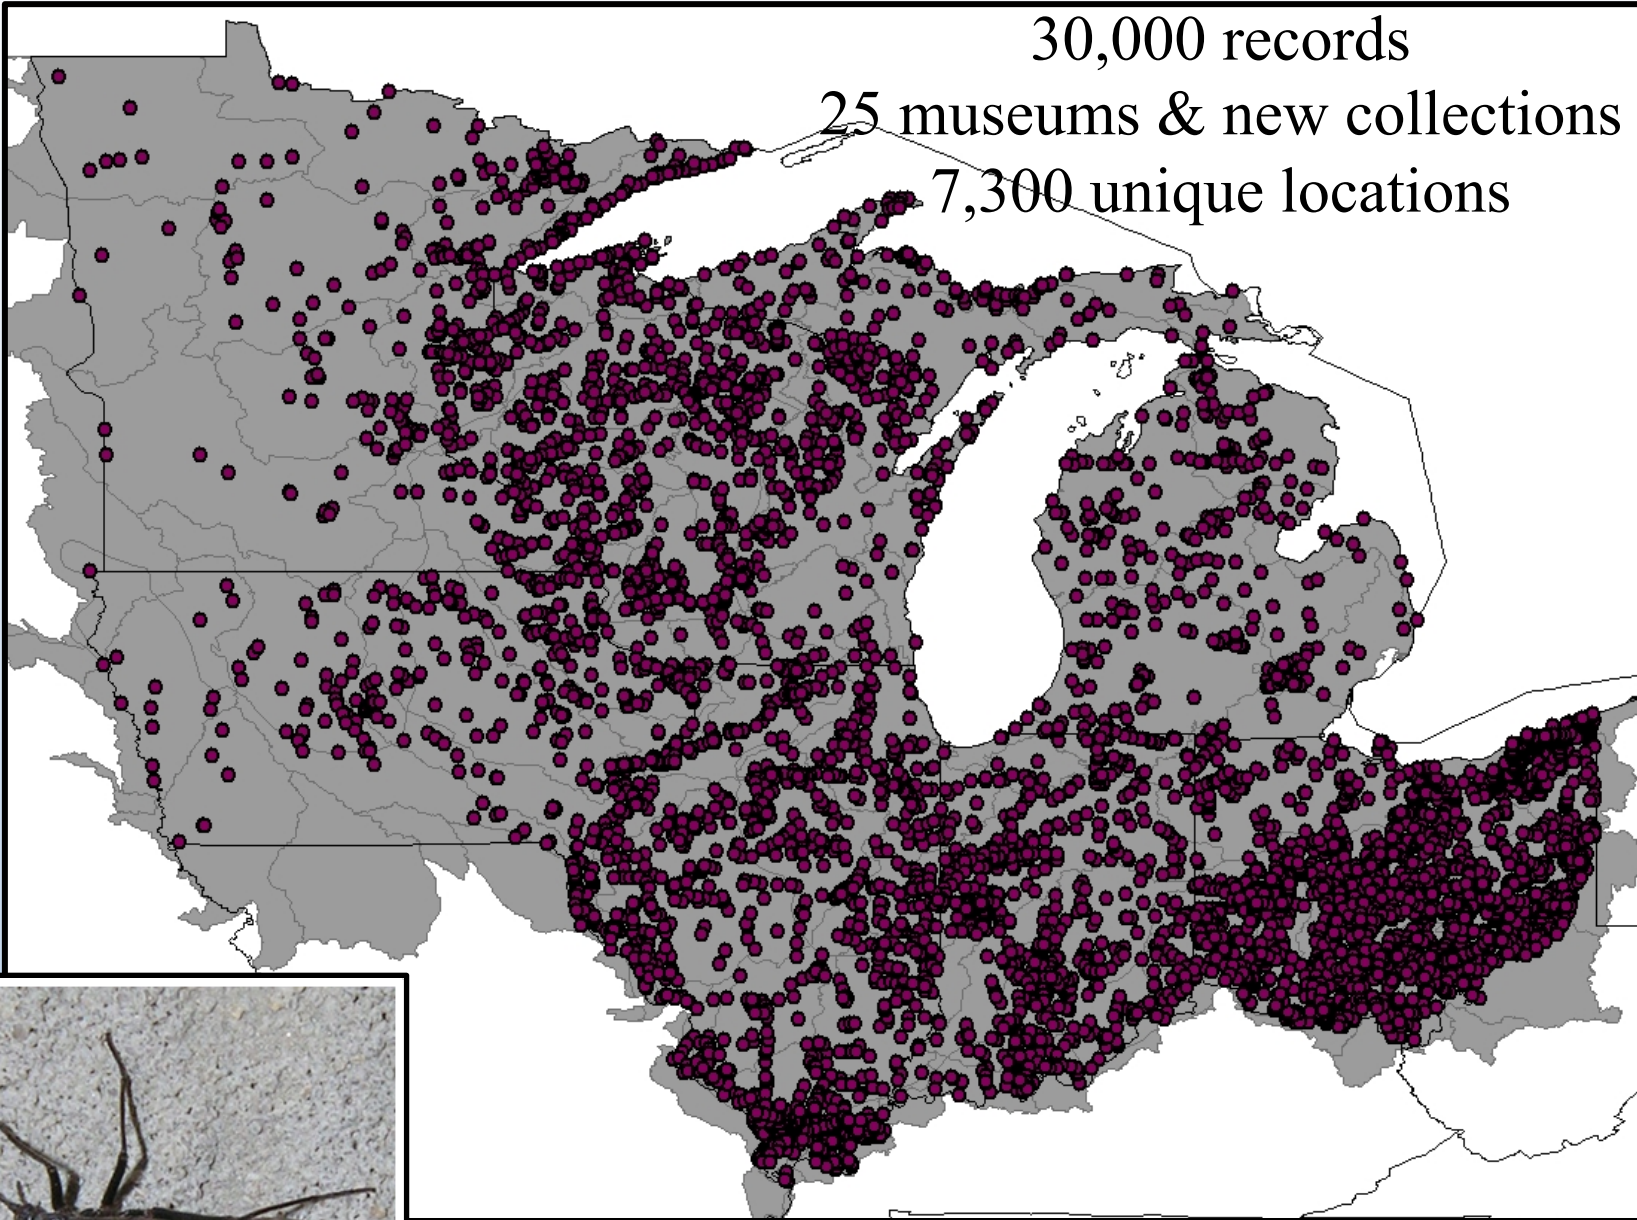

- No data withheld for validation
- Single record/species/HUC12
- Threshold for entry ≥ 14 HUC12s
- Richness from summing presences

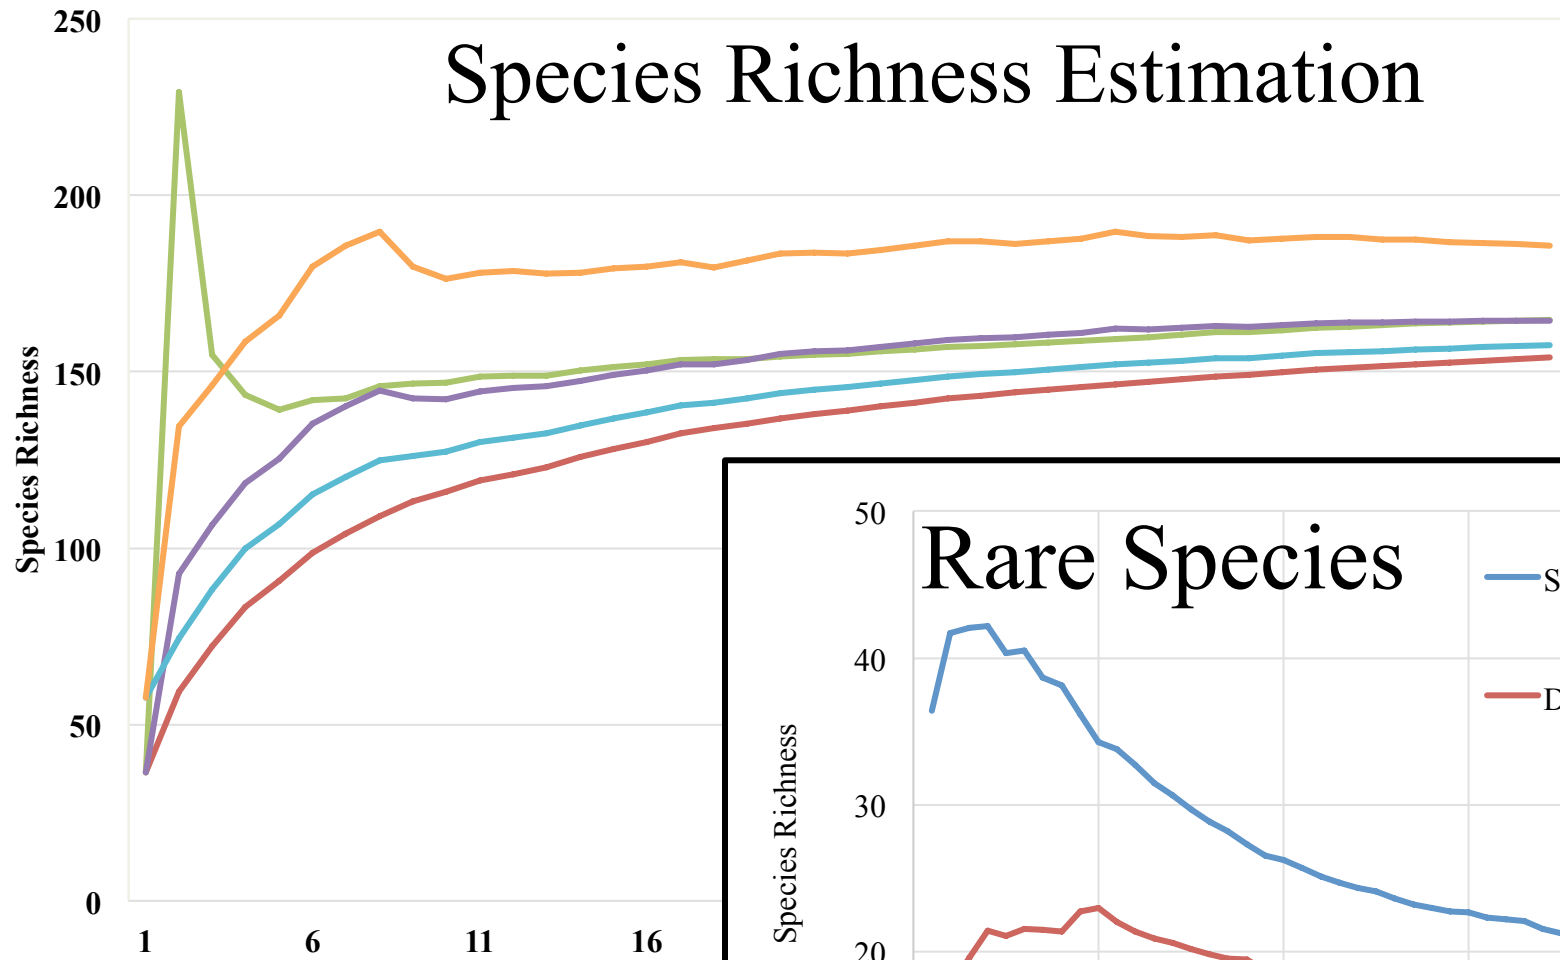

30,000 records

25 museums & new collections

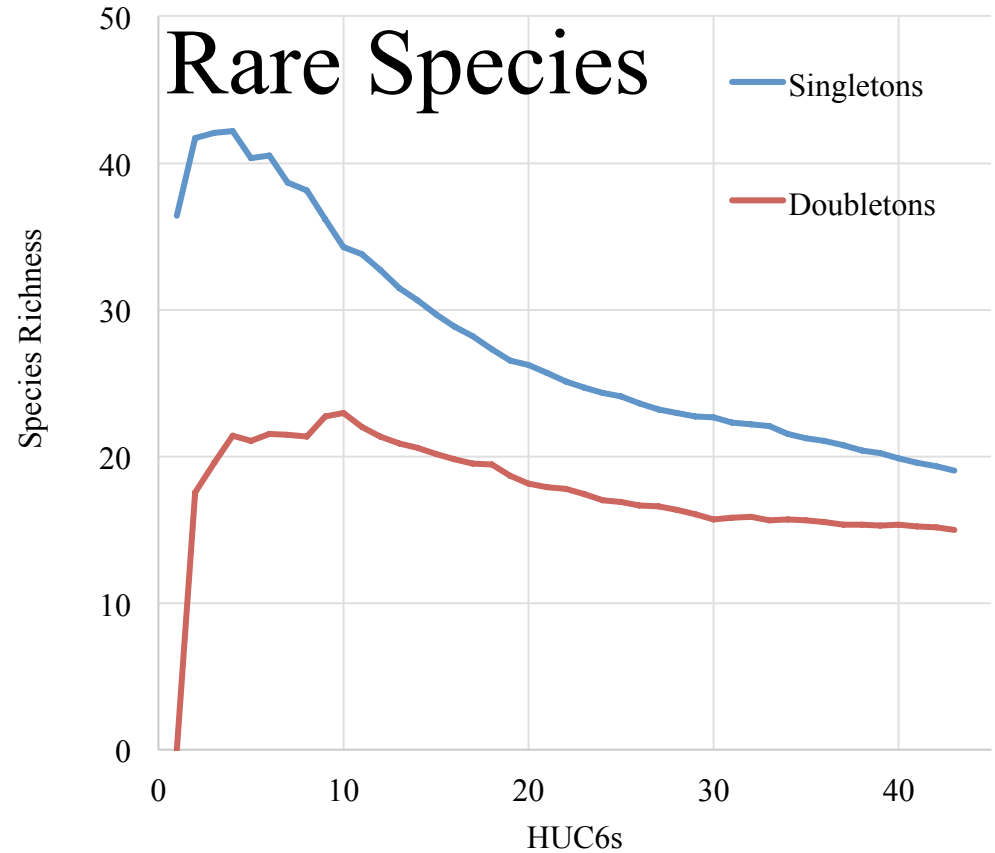

7,300 unique locations

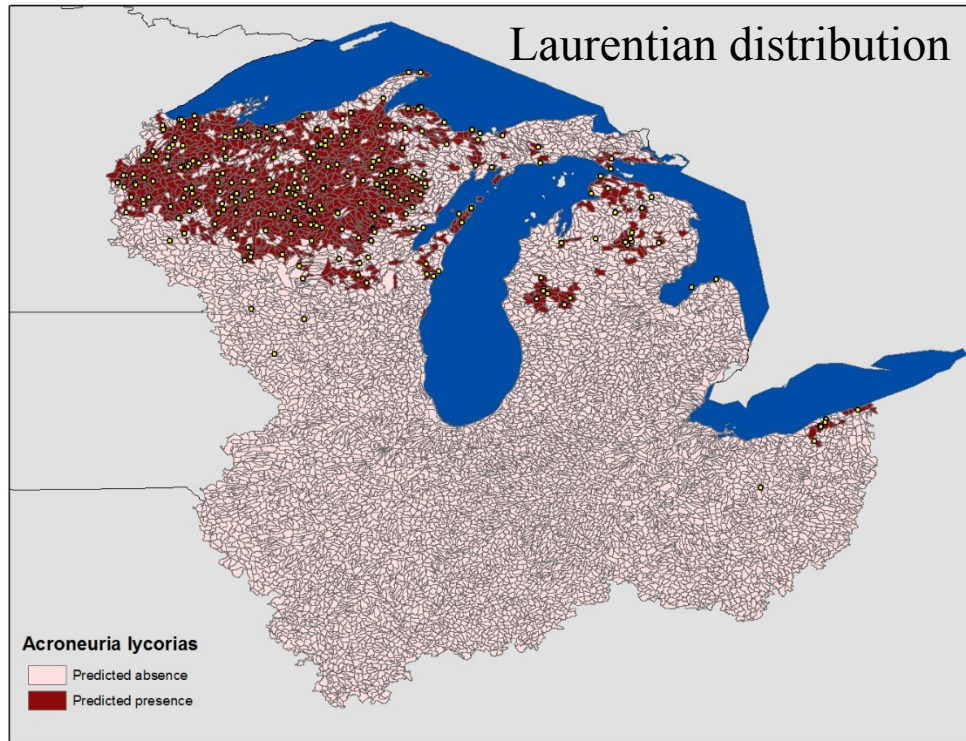

Species Richness Estimation

Rare Species

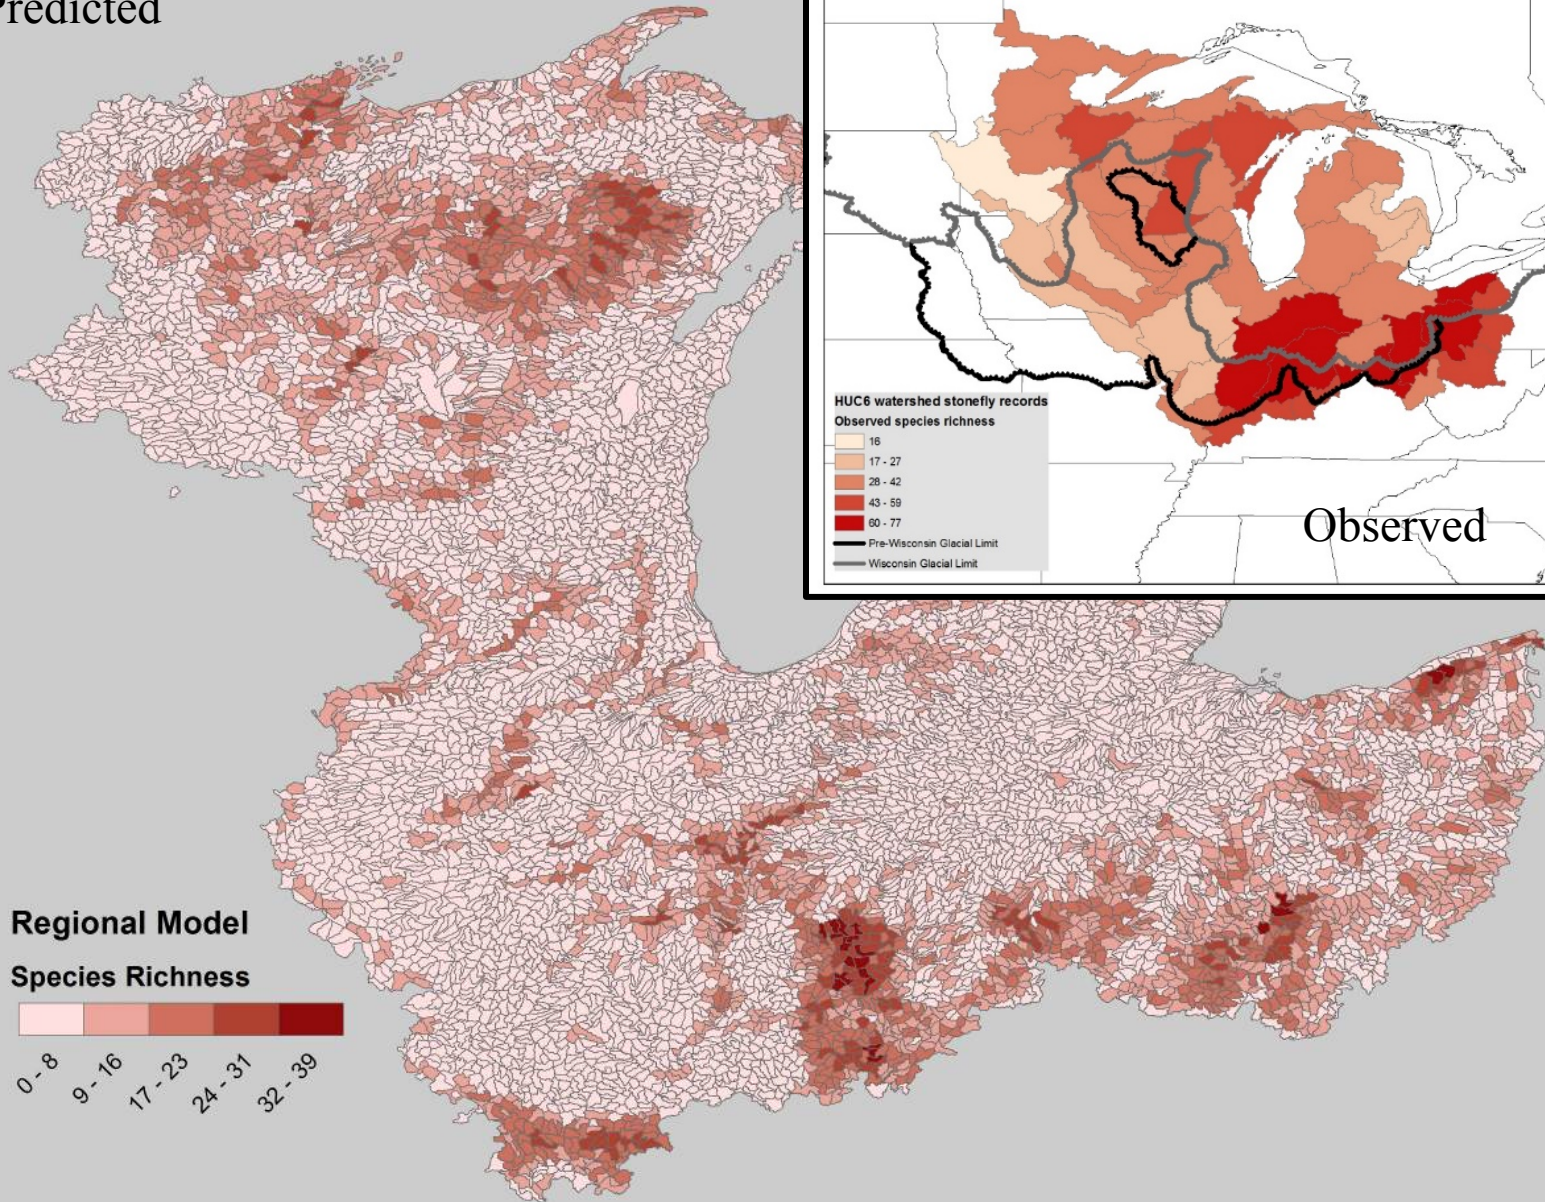

Full Models for 78 of 154 Species

Regional Species Richness Model

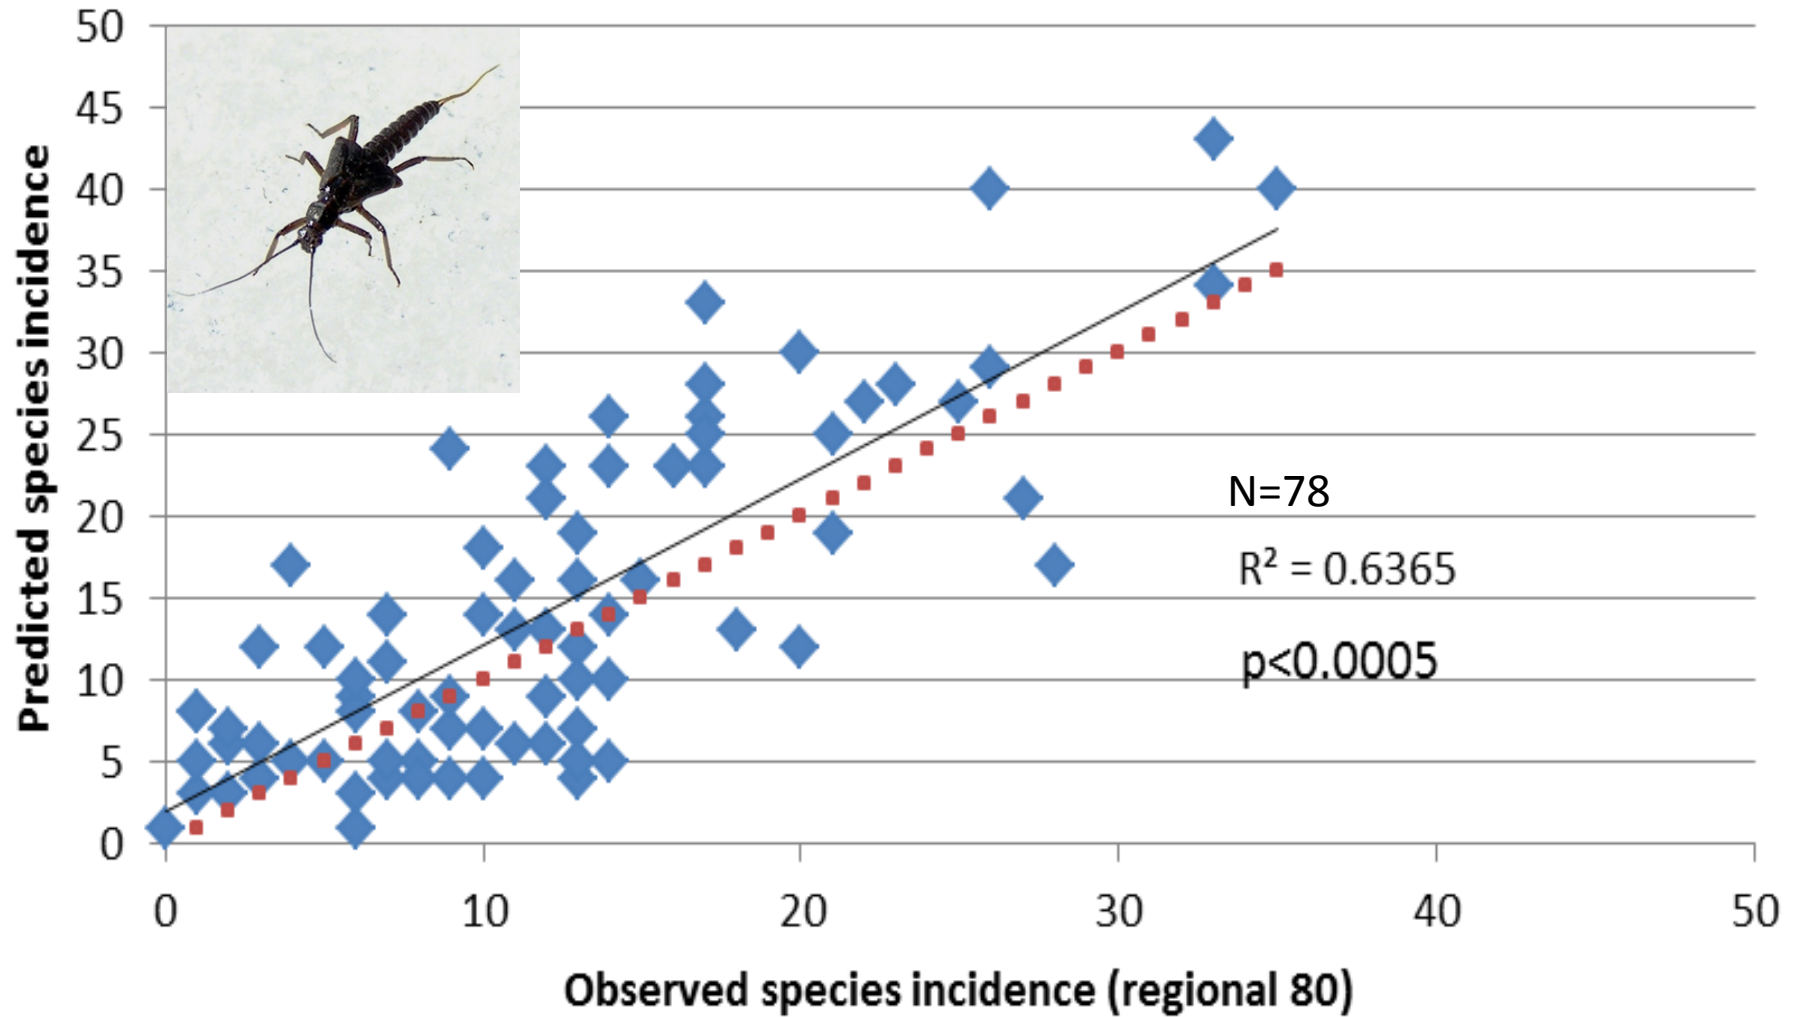

Predicted

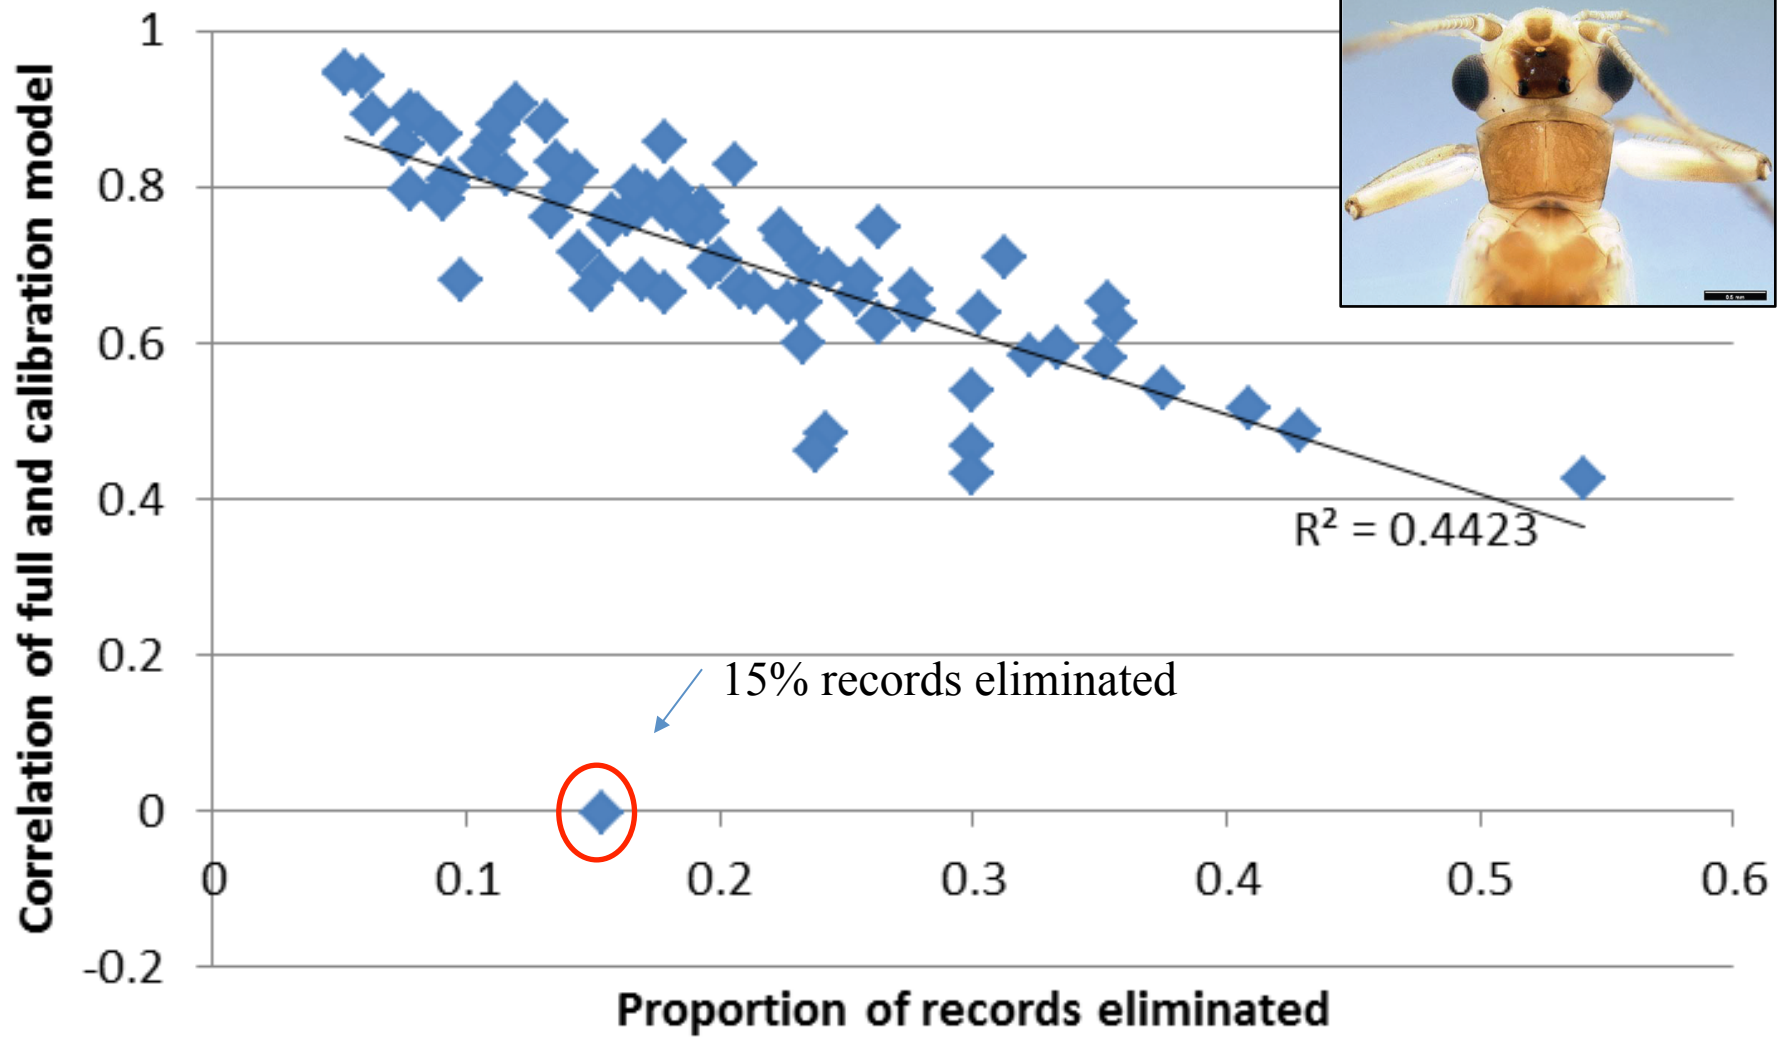

Model Calibration

- 80 “best” watersheds removed from **Full Model** to form **Calibration Model**
- Correlation of incidence between the calibration model and observed values in 80 watersheds
- Correlation of **Full & Calibration** model incidences per species

Calibration Model Performance: Incidence

Model Correlation vs. proportion records eliminated

One outlier, when removed, improves the R^2 to 0.69.

Conclusions

- Past distributions
 - Museum data provided >50% of 30K records for modeling, many were for areas where species no longer occurs
 - 78 of 154 species modeled
 - Species incidence well predicted
 - predicted richness followed observed richness patterns
- Much more than digitization needed to answer questions
 - >50 specimens not identified to species or incorrectly IDed
 - Much value added work necessary
 - New specimens were indispensable to answering questions
- Future research
 - Past and future (climate) models for 450 EPT in Midwest
 - Use “least-cost path analysis” and distr. model outputs to examine pathways and barriers to dispersal
